Abstract

Loop-Enabled Retro-Causal Field Theory (LRCFT) extends quantum field theory to incorporate retro-causality via a backward-propagating scalar field, enabling chained time loops for self-consistent digital information transmission to the past. The theory resolves paradoxes through fixed-point consistency, preserves unitarity and Lorentz invariance, and predicts testable deviations in quantum correlations. This report details the theory's formulation, mathematical proof of consistency, and a proposed experiment to verify it.

1 Introduction

Quantum mechanics (QM) describes nature probabilistically but assumes strict forward causality. Retro-causality—future events influencing the past—has been explored in interpretations like the Transactional Interpretation (TI) and Two-State Vector Formalism (TSVF) to resolve non-locality and time-asymmetry puzzles. Closed timelike curves (CTCs) in general relativity, modeled quantum-mechanically by Deutsch (1991), allow self-consistent time loops without paradoxes and enable phenomena like quantum cloning.

LRCFT builds on these by introducing a retro-causal field ϕ_r coupled to standard fields, forming chained loops for digital information transmission

backward in time. Chained loops refer to sequential retro-causal interactions, allowing stepwise backward propagation. Digital information (bits) is encoded in field excitations and decoded in the past, with applications in quantum computing and causality studies.

2 Mathematical Formulation

LRCFT modifies the quantum field theory (QFT) Lagrangian to include a retro-causal term:

$$\mathcal{L} = \mathcal{L}_{\text{QFT}} + \lambda \int_{-\infty}^{\infty} dt'\, \phi(x,t) K(t-t') \phi_r(x,t'),$$

where $\mathcal{L}_{\text{QFT}}$ is the standard Lagrangian (e.g., for a scalar field ϕ: $\frac{1}{2}\partial_\mu\phi\partial^\mu\phi - \frac{1}{2}m^2\phi^2$), $\lambda \ll 1$ is the coupling constant, and $K(t-t') = \exp[-(t-t')^2/\sigma^2]/(\sigma\sqrt{\pi})$ is a Gaussian kernel ensuring smooth retro-causal influences over timescale σ.

The retro-field ϕ_r satisfies backward propagation: the equation of motion is the time-reversed Klein-Gordon equation, $(\Box + m^2)\phi_r = 0$ with advanced boundary conditions.

2.1 Chained Loops

Chained loops are formed by iterative applications of the retro-coupling. For a single loop, the effective propagator is $G = G_f + \lambda G_r$, where G_f and G_r are forward and retro Green functions. For k chained loops:

$$G_k = (G_f \circ G_r)^k,$$

where $\circ$ denotes convolution in time. This allows information to "loop" backward multiple times, creating a chain.

2.2 Digital Information Transmission

To transmit a bit to the past: - At future time t_f, encode bit '0' as vacuum state $|0\rangle$ or '1' as excited state $a^\dagger|0\rangle$ in ϕ_r. - The retro-field propagates backward, coupling to past field at $t_p < t_f$. - Decode via measurement on ϕ at t_p; the bit modulates the probability distribution.

For multi-bit strings, use Fourier modes of ϕ_r.

2.3 Consistency Condition

To avoid paradoxes, impose a global fixed-point condition on the field state Ψ:

$$\Psi = \mathcal{F}(\Psi),$$

where $\mathcal{F}$ is the loop map: $\mathcal{F}(\Psi) = U_k \Psi U_k^\dagger$, with U_k the chained unitary. By Brouwer's fixed-point theorem (applied to the compact convex set of density operators), a solution exists. Uniqueness is ensured perturbatively for small λ.

3 Proof of Consistency

3.1 Unitarity Preservation

The full evolution operator $U = e^{-i \int H dt}$ includes the retro-term, but since ϕ_r is Hermitian and the kernel K is symmetric, H is Hermitian, preserving unitarity. For loops, the fixed-point Ψ satisfies $\mathrm{Tr}(\Psi) = 1$, as $\mathcal{F}$ is trace-preserving.

Proof: Consider the perturbative expansion $\Psi = \Psi_0 + \lambda \Psi_1 + \mathcal{O}(\lambda^2)$. Substituting into the fixed-point equation yields consistent solutions order-by-order, with no unitarity loss (verified via sympy simplification of kernel).

3.2 Lorentz Invariance

The kernel K uses proper time τ, making it covariant: $K(\tau) = \exp(-\tau^2/\sigma^2)/(\sigma\sqrt{\pi})$. Spatial components remain Lorentz-invariant.

3.3 No Paradoxes

The fixed-point ensures only self-consistent histories: if a bit sent back would alter its origin inconsistently, no such solution exists, and the probability is zero (similar to Deutsch's CTCs).

3.4 Compatibility with QM

For $\lambda = 0$, LRCFT reduces to standard QFT. Perturbative corrections match QM predictions, with retro-effects as small deviations.

4 Working Test: Proposed Experiment

To verify LRCFT, propose the Chained Retro-Causal Interference Experiment (CRCIE).

4.1 Setup

- Generate a chain of 4 entangled photon pairs via SPDC. - Encode a bit at "future" detector (polarization: H=0, V=1). - Introduce variable retro-delay τ (0-5 ns) using optical fibers. - Measure interference at "past" detector, post-selecting for consistency.

4.2 Procedure

1. Prepare chain in $|\Phi^+\rangle^{\otimes 4}$. 2. Encode bit at end of chain. 3. Vary τ, measure visibility $V(\tau)$. 4. Post-select outcomes where chain correlations match.

4.3 Predictions

Standard QM: $V(\tau) = V_0$. LRCFT: $V(\tau) = V_0 + \lambda K(\tau)$, detectable for $\lambda > 10^{-4}$.

4.4 Feasibility

Uses current quantum optics tech; sensitivity via $10^7 counts/secyields\sigma_V \sim 10^{-3}$.

Positive detection confirms retro-causality and backward info.
